

Soft Handoff and Uplink Capacity in a Two-Tier CDMA System

Shaline Kishore, Larry J. Greenstein, H. Vincent Poor, Stuart C. Schwartz

Abstract—This paper examines the effect of soft handoff on the uplink user capacity of a CDMA system consisting of a single macrocell in which a single hotspot microcell is embedded. The users of these two base stations operate over the same frequency band. In the soft handoff scenario studied here, both macrocell and microcell base stations serve each system user and the two received copies of a desired user's signal are summed using maximal ratio combining. Exact and approximate analytical methods are developed to compute uplink user capacity. Simulation results demonstrate a 20% increase in user capacity compared to hard handoff. In addition, simple, approximate methods are presented for estimating soft handoff capacity and are shown to be quite accurate.

Index Terms—CDMA, user capacity, macrocell, microcell, soft handoff

I. INTRODUCTION

In systems using code-division multiple access (CDMA), user capacity is enhanced by using *soft handoff*, [1]-[5]. By soft handoff we mean that a given user communicates simultaneously with two or more base stations until its path gain to just one of them is several dB stronger than its path gain to any other. This is in contrast to *hard handoff*, wherein the user communicates at any given time with only one base, selected according to some path gain criterion.

In [6], we examined a CDMA system consisting of a single macrocell in which a single *hotspot* microcell is embedded. Such a microcell might be installed to serve small regions of high user density with a low-cost, low-power base station. Using both analysis and simulation, we determined the uplink user capacity (i.e., the number of uplink users supported with a specified probability of success) of this two-tier system under the condition of hard handoff. Here, we address the same system when both bases serve each user (soft handoff), and we quantify the gain in uplink user capacity. The gain is relative to the hard handoff approach, wherein the base selected is the one having the largest path gain to the user terminal. We focus on the uplink direction because it tends to be the limiting direction, as we showed in [7].

Section II describes the system geometry and the underlying propagation and processing assumptions. Section III presents an exact criterion for determining uplink user capacity in ideal soft handoff, and compares the results to those for hard handoff [6]. Also presented are two simpler methods, based on an analytical approximation, and they are shown to be quite accurate. While our study is specific to a particular two-tier system in a highly dispersive multipath environment, extensions of our methods to other cases are possible, as we discuss in Section IV.

II. ASSUMPTIONS

As in [6], we assume a coverage region $\mathcal{R}$ (Figure 1) with a macrocell base at the origin of the coordinate system and a microcell base at a distance x_0 along the x axis. For concreteness in our computations, we assume the shape of $\mathcal{R}$ is a square of side S , with the macrocell base at the center. It was shown in [8], Ch. 4, that the uplink capacity for square and circular $\mathcal{R}$ are virtually the same; here, the square shape is assumed in order to simplify computations.

All system users desire a rate R and use a processing gain W/R , where W is the system bandwidth. We assume that the potential users are made up of two populations: One consists of low-density (LD) users, distributed uniformly over the entire coverage region; the other consists of high-density (HD) users, distributed uniformly over a small square area surrounding the microcell base. The side of this smaller square is $s \ll S$. We denote by P_h the probability that a randomly selected user is from the HD population. The probability that a user is from the LD population is, of course, $1 - P_h$. We call P_h the *hotspot density*.

The path gain, T , between either base and a user at a distance d is assumed to be

$$T = \begin{cases} H \left(\frac{b}{d}\right)^2 10^{\chi/10}, & d \leq b \\ H \left(\frac{b}{d}\right)^4 10^{\chi/10}, & d > b \end{cases}, \quad (1)$$

where b is the “breakpoint distance” [9] (in the same units as d) at which the slope of the dB path gain versus distance changes; χ is a zero-mean Gaussian random variable for each user distance, with standard deviation σ ; and H is a proportionality constant that depends on wavelength, antenna heights, and antenna gains. Note that T is a local spatial average, so that multipath effects are averaged out. There can be different values of b for the microcell and macrocell, and similarly for σ and H . The factor $10^{\chi/10}$ is often referred to

as lognormal shadow fading, which varies slowly over the terrain. Both χ and d are random variables for a randomly selected user.

In analyzing soft handoff performance, we will make the following assumptions: (1) Each user in the environment is processed by *both* bases, regardless of the user's path gains to the two bases.¹ (2) At each base, ideal RAKE processing is performed on each user's received signal in order to maximize diversity; (3) Each user-base path is "infinitely dispersive," meaning that there is a near-infinity of resolvable, comparable-strength multipaths on each link. Given (2) and (3), the receiver output signal sample for each user will be non-fading, just as if the link had a single path of fixed gain. We can therefore proceed by assuming the additive white Gaussian noise (AWGN) condition for each link, which simplifies the analysis. The implications of this assumption, and its relaxation, are discussed in Section IV.

III. ANALYSIS AND RESULTS

A. Exact Method

From the foregoing, we can proceed as though user i ($i = 1, 2, \dots, N$) has signal path gains $\sqrt{T_{Mi}}e^{j\phi_{Mi}}$ and $\sqrt{T_{\mu i}}e^{j\phi_{\mu i}}$ to the macrocell and microcell, respectively. This user transmits a signal at power P_i , which is controlled by the bases. The parameters ϕ_{Mi} and $\phi_{\mu i}$ are the phases of the path gains from user i to the macrocell and microcell bases, respectively. In the soft-handoff scenario studied here, both the macrocell and microcell bases receive, despread, and RAKE-combine the signal from each of the N users. There are, therefore, two output streams (one at the macrocell and one at the microcell) which contain a user's desired signal. Each of these two streams also contains interference from the $N - 1$ other users plus thermal noise.

The output streams at the macrocell and microcell bases are weighted by w_{Mi} and $w_{\mu i}$, respectively, and then summed. After combining, the overall output SINR (signal-to-interference-plus-noise ratio) of user i is

$$SINR_i = \frac{\frac{W}{R}S_i}{|w_{Mi}|^2 I'_{Mi} + |w_{\mu i}|^2 I'_{\mu i}}, \quad (2)$$

where

$$S_i = \left| w_{Mi}e^{j\phi_{Mi}}\sqrt{P_i T_{Mi}} + w_{\mu i}e^{j\phi_{\mu i}}\sqrt{P_i T_{\mu i}} \right|^2, \quad (3)$$

$$I'_{Mi} = \left(\sum_{j=1, j \neq i}^N P_j T_{Mj} + \eta W \right), \quad (4)$$

$$I'_{\mu i} = \left(\sum_{j=1, j \neq i}^N P_j T_{\mu j} + \eta W \right), \quad (5)$$

and ηW is the thermal noise power in the system bandwidth. This SINR equation implicitly treats the interference from each user j as if it is uncorrelated between bases. In fact,

the two interferences from user j are correlated, as they carry the same data. The combiner output voltage sample from user i is therefore proportional to

$$w_{Mi}\sqrt{P_i T_{Mi}}e^{j\phi_{Mi}} + w_{\mu i}\sqrt{P_i T_{\mu i}}e^{j\phi_{\mu i}}$$

and the squared magnitude has a cross-term proportional to the cosine of a path-gain-related phase. The phase term is uniformly random on $[0, 2\pi)$, and so the sum over $j \neq i$ of all cross-terms will converge to a mean of zero as N approaches infinity. For the values of N of interest here, substitution of this mean value is a very reasonable approximation; hence (2) applies.

The system studied here uses path-gain-weighted combining, i.e., it co-phases the two signals, via the phases of w_{Mi} and $w_{\mu i}$, and uses the following magnitudes for w_{Mi} and $w_{\mu i}$:

$$|w_{Mi}| = \frac{\sqrt{T_{Mi}}}{\sqrt{T_{Mi} + T_{\mu i}}} \quad \text{and} \quad |w_{\mu i}| = \frac{\sqrt{T_{\mu i}}}{\sqrt{T_{Mi} + T_{\mu i}}}. \quad (6)$$

Observe that $w_{Mi}^2 + w_{\mu i}^2 = 1$. Using these values and the assumed co-phasing, we can simplify (2):

$$SINR_i = \frac{\frac{W}{R}P_i(T_{Mi} + T_{\mu i})}{|w_{Mi}|^2 \sum_{j \neq i}^N P_j T_{Mj} + |w_{\mu i}|^2 \sum_{j \neq i}^N P_j T_{\mu j} + \eta W}. \quad (7)$$

We desire $SINR_i \geq \Gamma$, where Γ is the minimum required SINR for each user. Setting $SINR_i = \Gamma$ for all i leads to a matrix solution to the P_i 's that has the following form:

$$\mathbf{P} = \frac{\eta W}{K'} \mathbf{A}^{-1} \mathbf{1}, \quad (8)$$

where $K' = W/(R\Gamma)$ (note $K' + 1$ is the *single-cell pole capacity* [10]); $\mathbf{P} = [P_1 \ P_2 \ \dots \ P_N]^T$; $\mathbf{A}$ is an $N \times N$ matrix, with

$$A_{ii} = T_{Mi} + T_{\mu i} \quad \text{and} \quad (9)$$

$$A_{ij} = -\frac{1}{K'} \frac{T_{Mi}T_{Mj} + T_{\mu i}T_{\mu j}}{T_{Mi} + T_{\mu i}}, \quad i \neq j; \quad (10)$$

and $\mathbf{1}$ is an $N \times 1$ vector with each element equal to one. Note that the elements of $\mathbf{A}$'s are random variables, since each path gain T_{Mi} ($T_{\mu i}$) is determined by the random location and shadow fading of user i relative to the macrocell (microcell).

The two-tier system can support N total users if and only if the transmit power levels in (8) are positive, and this occurs if and only if the determinant of $\mathbf{A}$ is positive. The randomness of $\mathbf{A}$ implies that this *feasibility* of supporting N users occurs with some probability. The size of the random matrix $\mathbf{A}$ complicates the actual calculation of this probability of feasibility. Nevertheless, it is possible to use simulation methods to perform this calculation and gain insight into the capacity performance of the two-tier system under soft-handoff.

We performed simulations to find the 95% value of N using the following method: For the two-tier, two-cell system, with parameters as in Table 1, we performed 10,000 trials. In

¹This is an idealized assumption, since in practical systems only a subset of users (usually those on or near cell boundaries) is engaged in soft handoff.

each trial, the two path gains for each of N randomly-selected users were generated. These gains were then used to form the matrix $\mathbf{A}$ and compute its determinant. The feasibility (success) of the user set was determined by the sign of this determinant, and the probability of success over the 10,000 trials was computed for the selected N . The simulation program obtained the value of N for which 95% of trials yielded feasibility. The results are presented in Figure 2, where we plot N as a function of P_h , the hotspot density. We also plot the hard-handoff results from [6]. The plots show that user capacity varies with P_h , the maximum occurring at roughly $P_h = 0.5$. This is the density for which, on average, half of all users lies in the microcell coverage area. With this condition, the system contains roughly an equal number of users per base, which our previous work shows leads to maximum capacity [8], Chap. 4. Figure 2 also shows that for all P_h , the capacity is higher for soft handoff than for hard-handoff, and these gains are at most 20%.

B. Approximate Method

Due to the complexity in computing the exact user capacity for soft handoff (as outlined above), we now present an approximation method. We resort to the fiction that, in the denominator of (2), $|w_{Mi}|^2$ and $|w_{\mu i}|^2$ are the same for all users; we call these weights $|w_M|^2$ and $|w_\mu|^2$ and the common values are assumed to be

$$|w_M|^2 = \frac{1}{N} \sum_{i=1}^N |w_{Mi}|^2 = \frac{1}{N} \sum_{i=1}^N \frac{T_{Mi}}{T_{Mi} + T_{\mu i}} \quad (11)$$

and

$$|w_\mu|^2 = \frac{1}{N} \sum_{i=1}^N |w_{\mu i}|^2 = \frac{1}{N} \sum_{i=1}^N \frac{T_{\mu i}}{T_{Mi} + T_{\mu i}}. \quad (12)$$

In other words, the weights $|w_M|^2$ and $|w_\mu|^2$ are the average values of $|w_{Mi}|^2$ and $|w_{\mu i}|^2$ over the N users. Using these constant weights, the denominator in (2) is

$$D_i = |w_M|^2 \sum_{j=1}^N P_j T_{Mj} + |w_\mu|^2 \sum_{j=1}^N P_j T_{\mu j} - |w_M|^2 P_i T_{Mi} - |w_\mu|^2 P_i T_{\mu i} + \eta W.$$

This term is independent of i except for the third and fourth terms, which are small compared to the first and second terms for N large. If we ignore them, we obtain a common (i -independent) denominator given by

$$D = |w_M|^2 \sum_{j=1}^N P_j T_{Mj} + |w_\mu|^2 \sum_{j=1}^N P_j T_{\mu j} + \eta W \quad (13)$$

Assuming the denominator in (7) is replaced by D , and setting SINR_i to the required value of Γ , we obtain

$$P_i = \frac{1}{T_{Mi} + T_{\mu i}} \cdot \frac{D}{K'}. \quad (14)$$

Substituting this into (13), we obtain

$$D = \left[|w_M|^2 \sum_{j=1}^N \frac{T_{Mj}}{T_{Mj} + T_{\mu j}} + |w_\mu|^2 \sum_{j=1}^N \frac{T_{\mu j}}{T_{\mu j} + T_{Mj}} \right] \frac{D}{K'} + \eta W.$$

Solving for D , we get

$$D = \frac{\eta W K'}{K' - \left[|w_M|^2 \sum_{j=1}^N \frac{T_{Mj}}{T_{Mj} + T_{\mu j}} + |w_\mu|^2 \sum_{j=1}^N \frac{T_{\mu j}}{T_{\mu j} + T_{Mj}} \right]}. \quad (15)$$

Using (11)-(12) for $|w_M|^2$ and $|w_\mu|^2$, we see that this quantity (i.e., each P_i) is positive if and only if

$$\left(\sum_{i=1}^N \frac{T_{Mi}}{T_{Mi} + T_{\mu i}} \right)^2 + \left(\sum_{i=1}^N \frac{T_{\mu i}}{T_{Mi} + T_{\mu i}} \right)^2 < N K'. \quad (16)$$

This feasibility condition is far-simpler to examine than $\det(\mathbf{A}) > 0$.

We applied this approximation technique to the same system studied above. As before, we used 10,000 trials for each of several values of N . In each trial, we generated random user locations and shadow fadings for N users, leading to N pairs of $(T_{Mi}, T_{\mu i})$. Using (16), we then determined whether power control was feasible. Doing this for all trials, we were able to compute a probability of feasibility for the given N . Finally, we found the value of N corresponding to 95% probability. This N is plotted against P_h in Figure 2 ("Approx. 1"). We see that there is very good agreement; the approximation over-estimates capacity by at most three users, or roughly 7%.

C. Alternate Approximation Method

We now develop an even simpler analytical method to compute uplink capacity. We first note that (14) can be rewritten as

$$|A + jB|^2 < N K', \quad (17)$$

where

$$A = \sum_{i=1}^N \frac{T_{Mi}}{T_{Mi} + T_{\mu i}} \quad \text{and} \quad (18)$$

$$B = \sum_{i=1}^N \frac{T_{\mu i}}{T_{Mi} + T_{\mu i}} = N - A. \quad (19)$$

Since A and B are random variables, we can rewrite them as $A = E\{A\} + \delta(A)$ and $B = E\{B\} + \delta(B)$, respectively, where $\delta(A)$ and $\delta(B)$ represent random perturbations of A and B about their mean values, $E\{A\}$ and $E\{B\}$. Based on this new representation, (17) changes to

$$|X|^2 < N K', \quad (20)$$

where $X = |C + \delta(A) + j\delta(B)|$ and $C = E\{A\} + jE\{B\}$. Since $B = N - A$, we have, $\delta(B) = -\delta(A)$. We make this substitution and put the complex value $X = C + \delta(A) - j\delta(A)$ on a better basis by performing phase rotation. This is done by multiplying X by $(E\{A\} - jE\{B\})/|C|$. The rotated representation of X is then

$$X' = |C| + \frac{(2E\{A\} - N)\delta(A)}{|C|} - j \frac{N\delta(A)}{|C|}, \quad (21)$$

where we have used $B = N - A$. The feasibility condition in (20) can now be written as $|X'|^2 < N K'$.

A key step in this approximation is to first assume that $|X'| \approx |Re(X')|$. That is, assuming $|C|^2$ is large with respect to the standard deviation of $\delta(A)$ (as it is for large N), we ignore the quadrature term of X' . Thus, the feasibility condition is approximated as

$$|C| + \frac{(2E\{A\} - N)\delta(A)}{|C|} < \sqrt{NK'} \quad (22)$$

Next, we use the central limit theorem to approximate $\delta(A)$, which is a sum of i.i.d. random terms, as a zero-mean Gaussian variate. Let us represent the left side of (22) as Z , with mean μ_Z and standard deviation σ_Z . If μ and σ^2 are the mean and variance of each i.i.d. term in the sum A , (16), then it can be shown that

$$\mu_Z = |C| = N\sqrt{1 - 2\mu + 2\mu^2} \quad \text{and} \quad (23)$$

$$\sigma_Z = \frac{N^{3/2}\sigma|2\mu - 1|}{|C|}. \quad (24)$$

This implies that feasibility occurs with probability α or greater if and only if

$$N \leq \left(\frac{\sqrt{K'} - \frac{u_\alpha \sigma |2\mu - 1|}{\sqrt{1 - 2\mu + 2\mu^2}}}{\sqrt{1 - 2\mu + 2\mu^2}} \right)^2, \quad (25)$$

where u_α is the α -th percentile value of a zero-mean, unit-variance Gaussian variate. This approximation produces a simple, closed-form solution for the capacity supported in a two-tier system for a desired level of feasibility, α . Given α (assumed here to be 0.95) and values of μ and σ^2 , which can be determined using either simulation or analysis, user capacity can be simply estimated.

We used simulation to estimate μ and σ^2 for numerous values of P_h . Then, invoking (25) and rounding to the next lower integer, we obtained the result shown in Figure 2 ("Approx. 2"). We see that this new approximation overestimates the results from Section III-B by at most one user and exceeds the results from simulation by at most 4 users, corresponding to 10%.

IV. DISCUSSION AND CONCLUSION

We have devised three methods of soft handoff assessment that become progressively simpler to implement, in exchange for modest overestimations of capacity (less than 10%). Our results suggest that the uplink capacity benefit of soft handoff over hard handoff is minor for the two-tier, two-cell system we have examined. As shown in Fig. 2, the gain is no more than 20% for any value of hotspot density. However, this gain will be higher if the microcell base transmits and receives at a higher power, i.e., if H_μ is larger. With a larger H_μ , each user's total received power after path-gain-weighted combining will be higher, whereas under hard handoff, the attainable user capacity does not change as H_μ increases [8]. The gain due to soft handoff will also be higher if this mechanism is used in a system with multiple embedded microcells. Each embedded microcell offers an additional

path from the user and thus improves the total received power after path-gain-weighted combining. The techniques presented here can be used to determine the capacity gains when H_μ increases; the gain offered by multiple embedded microcells is a topic of future research.

Our results are obtained for highly dispersive channels and ideal RAKE receivers. For scenarios exhibiting less protection against multipath [11], soft handoff provides a micro-diversity benefit (against multipath fading) and a macro-diversity benefit (against shadow fading), so the soft handoff improvement will be greater. The key point, however, is that, as CDMA systems become more and more wideband, the capacity improvement due to soft handoff will become more modest.
